AI-driven vulnerability detection has advanced rapidly. On the CyberGym benchmark, LLMs went from discovering under 20 percent of vulnerabilities early last year to over 85 percent currently, yielding significantly higher-quality bug reports. Through recent scans of critical software, their models identified over 29,000 potential vulnerabilities. However, human review capacity created a bottleneck, allowing them to triage only about 6000 of them.

Recognising that exploits can now be developed in minutes, maintainers increasingly request bulk submissions of unverified findings to accelerate patching.

Inspired by Google's OSS-Fuzz, OSS Scanner complements Claude Security—Anthropic's enterprise code-scanning product—by bringing free, high-powered defensive capabilities directly to the open source community. Maintainers can opt to receive fully model-generated reports instantly without human review. While this automated approach enables faster and more frequent audits, it carries a risk of occasional invalid reports.

Visa open sources its AI cyber defence tool

Visa has open sourced its Visa Vulnerability Agentic Harness (VVAH), a model-agnostic framework designed to help security teams use AI for vulnerability discovery and remediation. The framework, developed from learnings from Anthropic's Project Glasswing, allows organisations to inspect, adapt and contribute to the code rather than relying on a closed security platform.

VVAH uses a multi-stage workflow to analyse software and identify potential attack paths. Its discovery pipeline maps the attack surface, performs deeper analysis and adversarial verification and then produces structured vulnerability reports.

The framework goes beyond vulnerability detection by supporting remediation and validation. After a vulnerability is identified, the system can assist with developing and validating fixes, while security and engineering teams remain responsible for reviewing findings, assessing severity and approving remediation paths. Visa describes this approach as using AI to accelerate security work while retaining human oversight at critical decision points.

The project is available through Visa's GitHub repository, giving security researchers and developers access to the implementation and an opportunity to adapt it to their own environments.

Nvidia launches agent safety platform

Nvidia has introduced the Nvidia Open Agent Safety Platform, an open software platform and reference system designed to add security controls around AI agents. It combines OpenShell, an open source secure runtime, with Sentry, a reference design that uses hardware-level monitoring to control agent activity. The platform aims to provide governance across the software, computing infrastructure, and robotic systems used by autonomous agents.

At the software level, OpenShell creates a security boundary outside the AI model and agent framework. It tracks agent actions and applies policies as the agent operates, allowing organisations to control access to tools, data, networks and other resources. OpenShell runs on Nvidia Vera CPUs and is designed so that support can also be extended to third-party platforms based on Arm and Intel processors.

The platform's hardware layer is provided by Sentry, an out-of-band watchdog designed to run on Nvidia BlueField-4 DPUs. If an agent attempts to operate outside its defined software boundaries, Sentry can quarantine and stop it within milliseconds. Its security functions use Nvidia DOCA to inspect requests and responses, verify agent identity, provide telemetry and enforce access policies.

The software, including OpenShell and its associated skills, is available through Nvidia's developer resources and GitHub.

Fujitsu launches open source quantum application package

Fujitsu has released its Open Quantum Application Research Package (OpenQARP) as open source software to simplify quantum application development. The package provides more than 100 software components, including Fujitsu-developed quantum algorithms, that can be combined to build applications rather than implementing algorithms from scratch.

At its core, OpenQARP includes more than 70 composable building blocks covering functions such as state preparation, ansatz layers and the Quantum Fourier Transform. More than 20 ready-to-run algorithms are also provided, including Subspace-Search Variational Quantum Eigensolver for noisy intermediate-scale quantum systems and quantum phase estimation for fault-tolerant quantum computing.

OpenQARP is designed to run across a range of computing environments. It can be installed on a standard Python-capable PC and can integrate with Nvidia CUDA-Q as a backend through a source build for GPU-accelerated execution. It can also run on Fujitsu's 40-qubit state-vector simulator, which uses 1024 PRIMEHPC FX700 systems equipped with A64FX processors.

The first open source release is v0.1.0 and is available under the Apache License 2.0, with the source code published on GitHub. By making reusable algorithms and development components openly available, the company aims to reduce the software effort involved in quantum application development and encourage broader experimentation.
